E-mail: hlovell@gmail.com

The monotypic Black-hooded Parakeet (*Nandayus nenday*) is native to palm groves, scrublands, and agricultural areas in the central interior of South America. Naturalized populations have developed in California and Florida as a result of individuals that were imported for the avicultural trade and then either subsequently escaped or were released (Pranty and Garrett 2003, Pranty and Lovell 2004). The first report of Black-hooded Parakeets in Florida was of two individuals at Eckerd College, St. Petersburg, Pinellas County, in 1969 (D. Goodwin pers. comm.). Since 1980, parakeet range and numbers have increased dramatically. We documented a population of 882 or more parakeets in nine peninsular counties from December 2002 through January 2004, and showed that the population increase approached exponential levels (Pranty and Lovell 2004). In 2004, the Florida Ornithological Society Records Committee ratified the Black-hooded Parakeet as an established exotic, and added the species to its official Florida list (Bowman and Greenlaw 2006). Since our paper was published, Black-hooded Parakeets have continued to expand their range along the central Gulf coast. Parakeets have recently colonized western Hillsborough County (Pranty 2009b, c; 2010) and northwestern Charlotte County (Pranty 2009a, b), and they have greatly increased their range and numbers in western Pasco County (e.g., 108 on the West Pasco CBC, 2 January 2009; NAS 2010). Black-hooded Parakeets now are the most common psittacid in parts of the Tampa Bay area (Pranty pers. obs.).

Black-hooded Parakeets breed and roost in natural cavities or those excavated by woodpeckers, in various natural or artificial substrates. Initial drafts of our manuscript on parakeet range and abundance (Pranty and Lovell 2004) included a section on nesting observations. Primarily to reduce the length of the manuscript, one reviewer recommended that we remove this section, and we complied. However, because the data that we had compiled represent the only information available on the nesting behavior of Black-hooded Parakeets in Florida, we present our data here.

#### METHODS

We sought to compile all known presumed or confirmed nesting observations of Black-hooded Parakeets in Florida. Historical information came from the original field data cards of the Florida Breeding Bird Atlas project (Kale et al. 1992), from Stevenson and Anderson (1994), and from the Florida Region reports in *American Birds*. To supplement these meager data, we posted requests to selected birding listservers in Florida during 2002 and 2009, and we communicated via e-mail with several birders (see acknowledgments). To gather nesting data of Black-hooded Parakeets in their native range, we posted a request to the ORNITH-L listserv, and this post was forwarded to the NEOORN-L listserv. Black-hooded Parakeets roost nightly inside cavities year-round (T. Mossbarger in litt., K. Tracey pers. comm.; Pranty pers. obs.), so we were careful to consider as active nests only those cavities that were occupied during mid-day. Many cavities were occupied on multiple occasions—several for weeks at a time (Table 1)—which strengthens our confidence that these cavities represented active parakeet nests rather than observations of parakeets prospecting potential nest sites.

#### RESULTS

We compiled 71 reports of presumed or confirmed nesting attempts by Black-hooded Parakeets in Florida since the 1980s (Table 1). All but one of these observations represent active nests; the single exception involved adults feeding juveniles. Most observations occurred during 2000-2002 and 2009, which represented the periods when we were actively gathering data on the parakeet. Dates of active nests range from 28 October to 23 July, with most nests (30 of 45 nests with dates; 66%) active in April, May, or June (Table 1). Active nests have been observed in 11 counties in Florida (Table 1), with recent activity observed in all but Bay, Lee, and Polk counties. Pinellas County, which contains by far the largest number of Black-hooded Parakeets (Pranty and Lovell 2004), accounted for 33 nesting reports, followed by nine in Broward County, seven each in Pasco and Sarasota counties, and lesser numbers in four other counties (Table 1). Some cavities, primarily those in utility poles, were used for two or more years; one cavity in Sarasota County was occupied for six consecutive years (Table 1). One palm snag in Broward County that supported an active parakeet nest in 2002 was bulldozed for the construction of a parking lot (Pranty and Epps 2002, S. Epps in litt.).

<sup>11</sup>Snag cut down; both nestlings rescued and raised in captivity.

<sup>12</sup>Same cavity used for six consecutive years.

Substrates are known for 61 presumed or confirmed nests in Florida: 34 (55%) in palm snags, 24 (40%) in wooden utility poles, two (3%) in slash pine (*Pinus elliottii*) snags, and one (1%) in an active Monk Parakeet (*Myiopsitta monachus*) nest (Table 1). Four species of palms have served as nesting substrates: Mexican fan palm (*Washingtonia robusta*;  $n = 13$ ), Cuban royal palm (*Roystonea regia elata*;  $n = 7$ ), cabbage palm (*Sabal palmetto*;  $n = 4$ ), and Chinese fan palm (*Livistona chinensis*;  $n = 1$ ), along with palms not identified to species ( $n = 9$ ). Cabbage palms are native to Florida, while the other palms have been imported for landscaping.

## DISCUSSION

Information about the nesting biology of Black-hooded Parakeets in their native range is limited. The only such observations known to Forshaw (1977), del Hoyo et al. (1997), and Juniper and Parr (1998) were by Naumburg (1930), who reported that Black-hooded Parakeets nested in corral posts in the state of Mato Grosso, Brazil, during the latter half of November. Clutch size (four eggs) was known from a single nest! During the 1990s, Tony Pittman (in litt.) found “many” Black-hooded Parakeet nests in Brazil that were built in palm snags and fence posts. Christina Morales (in litt.) studied Black-hooded Parakeets at Bajo Chaco, Paraguay, between September 1995 and January 1996. She found 32 nests: 31 in snags of caranday palms (*Copernicia alba*) and one in a snag of a yellow tabebuia (*Tabebuia caraiba*). Clutch size varied from one egg to seven eggs, with a mean of four eggs (C. Morales in litt.). Breeding success across all nests was 0.7 fledglings per nest. During her study, parakeets were single-brooded but laid replacement clutches if the first attempt failed (C. Morales in litt.).

Although nesting activity in Florida takes place primarily during spring and summer (April-June), Black-hooded Parakeets appear to have an extended breeding season in the state. Active nests have been observed in all months except August and September (Table 1). The two egg-dates available are sometime in February (2000) and 7 June (1989). In some cases, parakeets defended cavities for several weeks before incubation appeared to begin. Nesting substrates in Florida are similar to those observed in Brazil (Naumburg 1930, T. Pittman in litt.) and Paraguay (C. Morales in litt.).

Interactions between Black-hooded Parakeets and three other bird species have been observed in Florida. Parakeets successfully defended a nest cavity in Manatee County from European Starlings (*Sturnus vulgaris*) in July 2002 (W. Stinehelfer in litt.), and were seen “fighting starlings” over a potential cavity in Broward County (G. Cashin *fide* S. Epps in litt.). Competition over cavities between Black-hooded Para-

keets and Pileated Woodpeckers (*Dryocopus pileatus*) has been noted in Pinellas County (D. Margeson in Robbins et al. 2006, J. Fisher in litt.) and in Sarasota County (A. Bishop in litt., T. Mossbarger in litt.). Sometimes the parakeets were successful in defending the cavities from woodpeckers, while at other times the woodpeckers repelled the parakeets. Not related to nesting activity was an American Kestrel (*Falco sparverius*) that repeatedly dove on a Black-hooded Parakeet, which then flew up and chased the kestrel, at Fort De Soto Park, Pinellas County, on 11 March 2003 (I. Hernandez in litt.). A cavity in a utility pole in Pasco County used as a parakeet nest from April to June 2009 (Table 1) contained an abandoned honeybee (*Apis mellifera*) honeycomb on 14 November 2009 (Pranty photograph). This honeycomb had been removed by April 2010, when a pair of Black-hooded Parakeets again occupied the cavity (Table 1). Honeybees also temporarily usurped a utility-pole cavity in Pasco County during September–October 2009 that was occupied by Sun Parakeets (*Aratinga solstitialis*; Pranty and Lovell 2011). Given their reliance on suburban and urban areas, and considering the few, minor interactions noted here, it appears that the impacts of Black-hooded Parakeets in Florida to native species and habitats are negligible.

#### ACKNOWLEDGMENTS

We thank the following individuals for sharing their observations or for providing other assistance: Juan Barnett, Bill Boeringer, Allison Bishop, Jeff Bouton, Pam Bowen, Andrew Boyle, Dan Brooks, Rob Clay, Kate Coberly, Linda Cooper, Tom Davidowicz, Laurella Desborough, Jack Eitnir, Susan Epps, Judy Fisher, Lee Fitzgerald, Beth Forys, Diego Franco, David Goodwin, Roger Hammer, Irene Hernandez, Dart Humeston, Jackie Kern, Marianne Korosy, Renne Leatto, Don and Lorraine Margeson, Barbara Mathie, Tina Mossbarger, Kris Nelson, Mark Oberle, Tony Pittman, Peggy Powell, Susan Pulling, Diane Reed, David Roemer, Denise Rohde, Michelle Snyder, Wes Stinehelfer, Ken Tracey, Helen Warren, Ann Wiley, Tim Wright, and Wilma Zane. We are grateful to Christina Morales for graciously sharing her unpublished data from Paraguay, Don Margeson for supplying his photographs of parakeets and woodpeckers, and Steve Heinl for encouraging us to publish this paper. Jon S. Greenlaw and Michael L. Avery improved drafts of the manuscript.
