## Warbler tail spots

Charles H. Blake

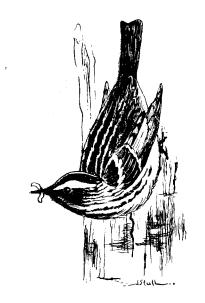

(Reprinted from EBBA News, Volume 29, No. 2, March 1966, with the author's permission. Tail feather sketches courtesy of Barbara Petorak.)

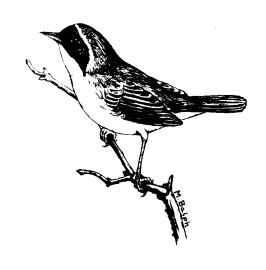

Many of our warblers have white (or yellowish) areas in, at least, the outer tail feathers. They are wanting in: Swainson's, Worm-eating, Orange-crowned, Nashville, Wilson's and Canada Warblers, as well as the [Common] Yellow-throat, [Yellow-breasted] Chat, and Seirus and Oporornis. Experience indicates that these spots in the outer tail feathers, when present, can be useful as auxiliary characters for confirming the identification of fall warblers. The accompanying diagrams show the patterns of eastern warblers, except the three great rarities: Bachman's, Kirtland's and Sutton's Warblers. These [latter] species have no special winter plumage.

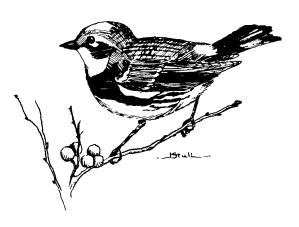

Some further remarks are in order. Closely related species (Bay-breasted and Blackpoll) tend to have nearly identical patterns. Differences caused by age or sex seem to be fairly minor (exception: spots almost wanting in the female Black-throated Blue). Measurement of the spot length in 447 Myrtles [Yellow-rumped], disregarding age and sex, shows a range of 15 to 27 mm but the mean is  $20.4 \pm 1.6$  mm. The span from 19 to 22 mm included 74% of the birds, so the distribution is well peaked. The white may extend to the tip (Palm) or stop short (Cape May, Myrtle). There may be a subterminal dark area next to the rhachis (Black-and-White) or no such area (Palm). A few species have white extending across the outer vane (Black-throated Green, Blackburnian, Prairie). Very narrow white margins on either vane are frequent in fall. These appear to wear away rather soon and are not here considered as part of the pattern.

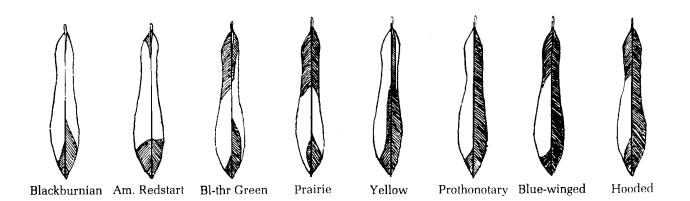

I am indebted to the North Carolina State Museum and the Museum of Comparative Zoology for loan of specimens.
